A Refinement Theory for Concurrent Object Oriented Languages

Abstract

A notion of refinement for concurrent object-oriented programs was originally presented in [3]. In this article we prove that the refinement relation associated to this notion is a congruence with respect to various standard programming language constructors, including parallel and sequential composition, conditionals, and non-deterministic internal choice. We also establish a weaker compositionality result for the atomic evaluation constructor, and illustrate how novel compositionality properties can be derived from the basic congruence property.

KEY WORDS: Formal methods, Object oriented programming, Refinement, Concurrency.

1 Introduction

The importance of formal methods for software development is nowadays significantly recognized. This is mainly justified by the high level of reliability achieved by complex systems developed using languages having a clear mathematical semantics [13, 12] and allowing formal proofs that design steps refine (satisfy) specifications [11].

However, among other factors, the industrial uptake of formal methods [4] depends crucially on adequate refinement theories and associated proof techniques to support the use of those methods in practice. In particular, formal (or even rigorous) software development is not at all practical unless there are theories justifying the compositional and stepwise refinement of specifications and implementations.

As originally presented in [3], based on the operational semantics of an arbitrary object-oriented language [12], we can directly define a notion of refinement for concurrent object-oriented programs written in that language. Moreover, [3] shows that this notion (relation) has some basic properties (e.g., reflexivity and transitivity) and comes up together with an effective proof technique for proving refinement. As illustrated in [3], this notion has been explored and proved to be quite suitable as a basis for formal stepwise development of concurrent object-oriented software, provided that the associated operational semantics satisfy some mild and natural conditions.

In this article we formalize those conditions and, provided that they are satisfied by the operational semantics, we prove that the refinement relation mentioned above is a congruence with respect to various standard programming language constructors, including parallel
and sequential composition, conditionals, and nondeterministic internal choice. We also establish a weaker compositionality result for the atomic evaluation constructor, which does not preserve refinement, and illustrate how novel compositionality properties can be derived from the basic congruence property. In this way we justify compositional development of concurrent object-oriented software and set the basis for a refinement calculus in the style of [11].

We formalize only the essential concepts necessary for deriving the compositionality results. Proofs are omitted for legibility and space reasons. Those proofs are presented in detail in [1], where one can see that they are not complicated and are based on very simple proof techniques such as case analysis and transition induction [10]; however, some of them are quite long and tedious. Indeed, the emphasis is not on presenting the proofs, but on presenting and analysing the results and its intuitions, in addition to describing the necessary mathematical machinery and the approach used to derive the results in a simple way. By following this approach anyone acquainted to that machinery can easily reproduce the results or adapt them for other contexts.

2 Operational Semantics

An object-oriented program (specification) defines a corresponding object-oriented system: the program describes the structure of the objects that the system may have, and the behavior of the methods and attributes associated to those objects. Object creation, object deletion, and method execution change the state of an object-oriented system. Such a state consists of information about existing objects in the system (database state), and expressions being concurrently evaluated.

The operational semantics [2] of an object-oriented language formalizes the notions of states and state transitions due to evaluating expressions. States are represented by pairs formed by an expression and a database state, represented as \((e, P)\), for an expression \(e\) and a database state \(P\). The first corresponds to the expressions being evaluated in the state, and the second contains information about the objects in the state. Respectively, we use \(\mathcal{T}_P\) and \(\mathcal{Db}(P)\) to denote the families of expressions (terms) and database states associated to \(P\). When not confusing, database states are just called "states". The initial database state associated to a specification (program) \(P\) is represented by \(\emptyset_P\), which contains only objects introduced by \(P\) and information about their respective attributes. Also, we use \(\text{Conf}(P)\) to denote the set of all configurations associated to a specification \(P\).

State transitions are specified by the transition relation

\[
\rightarrow_P \subseteq \text{Conf}(P) \times \text{Conf}(P),
\]

which actually defines the operational semantics of \(P\); it indicates how an expression is evaluated in a database state. When not confusing, we write \(\rightarrow\) instead of \(\rightarrow_P\). Similarly, the relation \(\rightarrow^*\) denotes the transitive, reflexive closure of \(\rightarrow\); also, we write \(P \nrightarrow\) if there is no \(P'\) such that \(P \rightarrow P'\) (this means that the expression in \(P\) cannot be further evaluated). Lastly, if \(P \rightarrow^* P'\) then we say that \(P'\) is a \(\rightarrow^*\)-derivative of \(P\); a corresponding terminology is used for \(\rightarrow\).

This transition relation is inductively defined over the syntax of expressions by inference rules which indicate how we can infer that two configurations are related (i.e., there is a
transition from one to the other), assuming that some others are related. For instance, the semantics of parallel composition can be defined by rules such as

\[
\begin{align*}
(e, D) &\rightarrow (e', D') \\
(e \mid f, D) &\rightarrow (e', f, D') \\
(v \mid e, D) &\rightarrow (e, D)
\end{align*}
\]

where \( v \) is a “fully evaluated expression”—an object identifier or an evaluated functional expression, such as an integer number, a character, etc. Of course, it is also necessary to have similar symmetric rules for evaluation of the argument on the right of the composition, indicating that the evaluation of the expressions can be freely interleaved.

A nondeterministic external choice constructor can be specified by the rules

\[
\begin{align*}
(e, D) &\rightarrow (e', D') \\
(e \quad f, D) &\rightarrow (e', D') \\
(v \quad e, D) &\rightarrow (v, D)
\end{align*}
\]

and similar symmetric ones, which indicate that transitions from the choice between two expressions correspond to transitions from one of the expressions. Note that a fully evaluated argument may be chosen by the choice without changing the database.

We can also define the semantics of an atomic evaluation constructor using rules such as the following:

\[
\begin{align*}
(e, D) &\rightarrow^* (v, D') \\
([e], D) &\rightarrow (v, D') \\
\text{terminating}((e, D)) &\rightarrow (e, D)
\end{align*}
\]

where we say that a configuration is terminating if there is no infinite sequence of \( \rightarrow \) transitions from it. Intuitively, the atomic evaluation of an expression corresponds to its full evaluation in only one step (transition). So if the evaluation of the expression to be atomically evaluated does not terminate, the atomic expression does not terminate as well. In fact, it behaves as a divergent process that does not modify the state.

The semantics of other constructors such as \( _;_ \) (sequential), \( \text{if.then.else.fi} \) (conditional) and \( \text{result;_;} \) (evaluates its first argument and then evaluates the second one, yielding the value resulting from the evaluation of the first) can be formally defined following the same lines above. Contrasting, the semantics of method and attribute evaluation, and also object creation and deletion, will not even be discussed in this article since it may vary a lot depending on the language, and it is not directly relevant to the derivation of the compositionality results that we will present. The semantics of those aspects are formally specified for a specific language in [2], for example.

3 Refinement

Based on the operational semantics of an arbitrary object-oriented language, the refinement notion originally presented in [3] considers refinement of states, expressions, and programs written in that language. In this article we discuss only refinement of states and expressions. Basically, a state \( P \) is simulated by a state \( Q \) if whatever can be observed by performing experiments with \( Q \) can also be observed by performing the same experiments with \( P \). In this case, if experiments are done with \( Q \), we cannot detect whether \( Q \) or \( P \) is being used, even though the experiments done with \( P \) might let us make more observations than if \( Q \) were used.
The only kind of experiment that we can make with object-oriented systems is to invoke visible operations (i.e., methods, attributes, and object creation and deletion routines) with arbitrary arguments. This results in a new state having the invoked operation as one of the expressions to be evaluated. Here are the aspects that we can observe from a state $P$:

1. the values of visible attributes of the objects in $P$;
2. the results yielded by the expressions being evaluated in $P$; and
3. whatever can be observed by performing experiments with the states that can be immediately reached from $P$ due to the execution of the expressions in $P$.

According to the last item and the notion of simulation we can conclude that if $P$ is simulated by $Q$ then states immediately reached from $Q$ simulate states immediately reached from $P$. However, a better definition of simulation can be obtained if we relax this strong correspondence between state transitions. In fact, it is only important that states immediately reached from $Q$ simulate states eventually reached from $P$. This is enough because in this case the observations that we can make from $Q$ are equivalent to observations that we can make from $P$ when we fail to observe some intermediate states. This still implies that the observable behavior associated to $Q$ is a particular case of the observable behavior associated to $P$; that is the essence of simulation.

Note that both notions of simulation discussed so far depend only on the notions of experiment and observation. Indeed, one state might simulate another even if they have different (internal) structures, and are associated to systems specified by different specifications. However, the experiments and observations should be meaningful for both systems. In general, given states $P$ and $Q$ respectively related to specifications $P$ and $Q$, $Q$ may only simulate $P$ if the observations and experiments introduced by $P$ are also introduced by $Q$. Only in this way we can compare the effects of performing the same experiment with $P$ and $Q$.

3.1 Simulations

Based on operational semantics, now we formalize the finer notion of simulation, which was originally presented in [3]. First let $E(P)$ denote the set of experiments associated to a specification $P$. Also let $FE(e)$ indicate that the expression $e$ is fully evaluated, according to a specification $P$ that should be understood from the context where $FE(e)$ is used; otherwise, we write $FE_P(e)$. Furthermore, for fully evaluated terms $p$ and $q$ respectively related to specifications $P$ and $Q$, assume that equality is denoted by $p =_{(P,Q)} q$; it holds if $p$ and $q$ are the same object identifiers or if they are the same element of an ADT that is defined by both $P$ and $Q$.

Assuming that the observations and experiments introduced by a specification $P$ are also introduced by a specification $Q$, the relation of simulation between states of $P$ and $Q$ is defined as the union of all relations $S \subseteq Conf(P) \times Conf(Q)$ such that $(P, Q) \in S$ implies the following:

1. Whenever $Q \rightarrow Q'$ then, for some $P'$, $P \rightarrow^* P'$ and $(P', Q') \in S$.
2. If $Q \not\rightarrow$ then, for some $P'$,
(a) $P \rightarrow^* P'$; 
(b) $\mathcal{F}\mathcal{E}_P(p') \Leftrightarrow \mathcal{F}\mathcal{E}_Q(q)$; 
(c) if $\mathcal{F}\mathcal{E}_P(p')$ then $p' =_P Q$; and 
(d) $(P', Q) \in \mathcal{S}$.

3. For any experiment $\text{exp} \in \mathcal{E}(P)$, whenever $\langle \text{exp}, Q \rangle \rightarrow^* Q' \Rightarrow$ then, for some $P'$,

(a) $\langle \text{exp}, P \rangle \rightarrow^* P'$; 
(b) $(P', Q') \in \mathcal{S}$; and 
(c) $\langle (p, P'), (q, Q') \rangle \in \mathcal{S}$.

where $P$ and $Q$ denote configurations, $P$ and $Q$ denote their respective database states, and $p$ and $q$ denote their respective expressions. Relations having those special properties are called $(P, Q)$-simulations.

Item 1 above says that any state immediately reached from $Q$ is related to some state that might eventually be reached from $P$. Condition 2 indicates that if the expression in $Q$ cannot be further evaluated then the expression in $P$ might eventually reach the same situation; when this happens, the resulting states will be related by $\mathcal{S}$ and the results yielded by the evaluation of the expression in $Q$ will also be yielded by the evaluation of the expression in $P$. In other words, the results of the evaluation of expressions in $Q$ might eventually be observed from $P$.

Condition 3 says that performing the same experiment with $Q$ and $P$ leads to states related by $\mathcal{S}$; by condition 2, this implies that the experiments yield the same results when performed in both states. Furthermore, if an experiment cannot be performed with $Q$ (its corresponding operation is not enabled, because it cannot be executed in a particular state), then performing the same experiment with $P$ results in a state related to $Q$ by $\mathcal{S}$; this usually means that the experiment cannot be performed with $P$ as well.

Those conditions reflect the ideas that we have introduced about simulation of states. However, they are based on a central assumption: operations used as experiments are atomic and terminating. Note that this does not imply that all available methods have to be atomic and terminating; indeed, nonatomic and nonterminating methods can be defined as hidden operations. In [3], this assumption is analyzed and justified.

3.2 Refinement of States

Note that if the pair $(P, Q)$ is in a $(P, Q)$-simulation then whatever can be observed by performing experiments with $Q$ can also be observed by performing experiments with $P$; this guarantees that one state simulates another. In fact, we say that a state $Q \in \text{Conf}(Q)$ simulates (or refines) a state $P \in \text{Conf}(P)$, denoted $P \sqsubseteq_{(P, Q)} Q$, if there is a $(P, Q)$-simulation containing the pair $(P, Q)$. Formally,

$$\sqsubseteq_{(P, Q)} = \bigcup \{ \mathcal{S} \mid \mathcal{S} \text{ is a } (P, Q)\text{-simulation} \}.$$ 

A direct result from this definition is the following:
Theorem 3.1 Assuming that the observations and experiments introduced by a specification \( P \) are also introduced by a specification \( Q \), the refinement relation on states \( \Xi_{(P,Q)} \) is the largest \((P, Q)\)-simulation. □

This was proved in [3]. It is also easy to check that the identity relation on configurations of the same program is a simulation, and that \( \Xi_{(P, P)} \) is reflexive and transitive; actually, we have that \( P \Xi_{(P, O)} O \) and \( O \Xi_{(O, Q)} Q \) imply \( P \Xi_{(P, Q)} Q \).

From the definition above we conclude that in order to prove that a state \( P \) is simulated by a state \( Q \), it is enough to find a simulation containing the pair \((P, Q)\). In fact, this is a very effective proof technique which makes proofs easier. In order to find a candidate simulation relation it is necessary to have some knowledge about the behavior of expressions and the relation between different representations for object states. After a candidate is found, it remains to check the conditions from the definition of simulation; that is a routine task which requires only the application of the transition rules of the operational semantics and checking whether the resulting states are related. Hereafter we let \( P \Xi_{(P, Q)} Q \) hold whenever \((p, P) \Xi_{(P, Q)} (q, Q)\) holds for some \( p \) and \( q \).

3.3 Refinement of Expressions

Based on the notion of refinement of states, we can define refinement of expressions. First recall that the initial database state associated to a program \( P \) is represented by \( \emptyset P \). Also, assume that states reached by performing an arbitrary (possibly empty) sequence of experiments with an initial state are called reachable (database) states.

For expressions \( p \) and \( q \) respectively related to specifications \( P \) and \( Q \), we say that \( p \) is refined by \( q \) when the evaluation of \( p \) in any reachable state \( P \) of \( P \) is simulated by the evaluation of \( q \) in a state \( Q \) reached from \( \emptyset O \) by performing the same sequence of experiments used to reach \( P \). (By the definition of simulation, this already considers that the evaluation of the expressions might be interfered by experiments.) Hence, when \( P \) and \( Q \) are the same specification, \( p \) is refined by \( q \) if the evaluation of \( p \) in any reachable state is simulated by the evaluation of \( q \) in the same state.

By analysing the definition of simulation of states, it is easy to check that an alternative way of expressing the ideas above is saying that \( p \) is refined by \( q \) if the evaluation of \( q \) in the initial state of \( Q \) simulates the evaluation of \( p \) in the initial state of \( P \). So, for specifications \( P \) and \( Q \), an expression \( q \in T_{Q} \) simulates (or refines) \( p \in T_{P} \), denoted \( p \Xi_{(P, Q)} q \), if

\[
(p, \emptyset P) \Xi_{(P, Q)} (q, \emptyset Q),
\]

The reflexive and transitive properties of refinement of states are also valid for this definition of refinement of expressions.

4 Refinement Theory

Now we develop a theory in order to show that the relation of refinement of expressions introduced in the previous section is a congruence with respect to most constructors introduced in Section 2; that is, choosing parallel composition as example, we are interested in proving that

\[
p \Xi_{(P, Q)} q \quad \text{implies} \quad p \parallel o \Xi_{(P, Q)} q \parallel o,
\]
for any expression o formed by experiments of P and most of the programming language constructors introduced in Section 2.

In fact, the congruence property only holds for contexts formed by visible operations (experiments). This is what should be expected for any notion of refinement based on the observational behaviour of states with respect to a restricted group of visible operations. This is definitely the case of the notion of refinement introduced in the last section (see condition 3c of the definition of simulation). So there is no guarantee that the evaluation of a hidden operation in two states related by \( \sqsubseteq \) will not have completely different observable effects.

The congruence property of refinement of expressions is what supports the compositional verification and derivation of implementations; that is essential for formal development of large systems. But note that this only supports compositionality in the small (i.e., regarding expressions and their composition, as considered in [10]). Compositionality in the large (i.e., regarding modules and their composition [5]) should be supported by a congruence property of refinement of programs (see [3] for the details) with respect to module interconnection operations (such as module importation); however, this is out of the scope of this work which does not consider the semantics of module systems.

In order to derive the compositionality results we proceed as follows. First we formalize the constraints on experiments informally described at the end of Section 3.1. Those constraints allow us to prove that \( \sqsubseteq_{(P,Q)} \) includes the identity on experiments whenever there is a \((P,Q)\)-simulation relating initial states; that is, for any experiment \( \exp \), \( \exp \sqsubseteq_{(P,Q)} \exp \) whenever there is a \((P,Q)\)-simulation relating initial states. We also extend this result for composition of experiments using some of the programming language constructors mentioned in Section 2. It then becomes easy to derive the desired congruence result; we consider each constructor separately.

### 4.1 Experiments

As discussed in Section 3.1, experiments should be terminating and atomic. An expression \( e \in \mathcal{T}_P \) is terminating, denoted \( \downarrow_P e \), if \( \langle e, D \rangle \) is terminating for any database state \( D \in \mathcal{D}b(P) \), where a configuration is terminating if there is no infinite sequence of \( \downarrow_P \)-transitions from it. We drop the subscript from \( \downarrow \) when it is not confusing.

Atomicity is not only achieved by ensuring that an expression is fully evaluated in one \( \rightarrow \)-transition. In fact, we consider that the atomic evaluation of an expression can take many transitions, as long as the only (if any) transition that depends on the state or corresponds to a choice is the last one; also, such a transition must yield a fully evaluated expression. Note that this still guarantees that any access to the database and any choices are made in only one \( \rightarrow \)-transition; no information is lost by the other transitions. In order to formalize those ideas, we introduce the relation \( \Rightarrow \), which indicates that an expression evaluates to another in one \( \rightarrow \)-transition without accessing the database state nor making choices. Here is the formal definition:

\[
P \Rightarrow_P q
\]

if, for any database state \( D \in \mathcal{D}b(P) \),

\[
\langle p, D \rangle \rightarrow_P \langle q, D \rangle \text{ and } \langle p, D \rangle \rightarrow_P O \Rightarrow O \equiv \langle q, D \rangle,
\]
where \( \equiv \) is the identity on configurations. An obvious extension of \( \models \) for states is defined as follows:

\[
P \models_P Q
\]

if

\[
p \models_P q \text{ and } P \rightarrow_P Q,
\]

assuming that \( p \) and \( q \) are respectively the expressions in \( P \) and \( Q \). (Note that \( P \models Q \) imply \( P \equiv Q \), where \( P \) and \( Q \) are respectively the database states in \( P \) and \( Q \), and \( \equiv \) denotes the identity on database states.) We drop the subscripts from those relations when not confusing. Also, when \( P \models Q \) does not hold, we write \( P \not\models Q \). A similar notation is used for the associated relation on expressions. Lastly, the reflexive and transitive closure of \( \models \) is represented by \( \models^+ \).

We can then formalize the constraint on experiments, where \( \mathcal{F}_E(P) \) is an abbreviation for \( \mathcal{F}_E(p) \): \( \text{exp} \in \mathcal{E}(P) \) implies \( \downarrow_P \text{exp} \) and, for any \( D \in \mathcal{D}(P) \), whenever \( \langle \text{exp}, D \rangle \rightarrow_P O \) then either

\[
\langle \text{exp}, D \rangle \models^+_P O
\]

or for some \( Q \),

\[
\langle \text{exp}, D \rangle \models^+_P Q \rightarrow_P O \text{ and } \mathcal{F}_E(O).
\]

When reasoning about refinement involving two specifications, this property of experiments should be valid for experiments of both specifications.

### 4.1.1 Transition Induction

The relation \( \models^+ \) can be formally defined by the following inference rules:

\[
\begin{array}{c}
p \models^+ p \\
p \models^+ o \quad o \models q \\
\end{array}
\]

Hence any transition \( p \models^+ q \) can be justified by a proof tree constructed using those rules. This allows us to prove properties of a \( \models^+ \)-transition by induction on the depth of proof trees. This is a well known proof technique extensively used in [10], where it is called proof by transition induction; it will be quite useful here too. The same technique can also be used to prove properties of \( \rightarrow \)-transitions.

Using this proof technique, we now derive a property of \( \models^+ \) that will be useful for proving some results that will be presented later. Informally, if \( p \models^+ q \) then, for any database state \( D \), there is a unique sequence of transitions from \( \langle p, D \rangle \) to \( \langle q, D \rangle \), since during the evaluation of \( p \) to \( q \) the database state cannot be modified and no choices can be made. So, whenever \( \langle p, D \rangle \rightarrow \rightarrow_P O \) then either \( O \) is one of the states in the sequence of transitions from \( \langle p, D \rangle \) to \( \langle q, D \rangle \), or \( O \) is a \( \rightarrow^+ \)-derivative of \( \langle q, D \rangle \). This is formalized by the following lemma.

**Lemma 4.1** If \( p \models^+_P q \) then, for any \( D \in \mathcal{D}(P) \), whenever \( \langle p, D \rangle \rightarrow^+_P O \) then

\[
\langle q, D \rangle \rightarrow^+_P O \text{ or } O \models^+_P \langle q, D \rangle.
\]

\(\square\)
4.1.2 Properties of Experiments

Using Lemma 4.1, we can derive a direct consequence of the constraint on experiments: during the evaluation of an experiment, any transition that makes a choice or access the database leads to a fully evaluated state. This is formalized by the following lemma.

Lemma 4.2 Let \( \text{exp} \in \mathcal{E}(P) \). Whenever \( (\text{exp}, D) \Rightarrow_{P} O \rightarrow_{P} P \) and \( O \neq_{P} P \) then

\[
P \neq_{P} \text{ and } \mathcal{F}\mathcal{E}_{P}(P).
\]

Motivated by condition 3c of the definition of simulation and the atomic nature of experiments, we now proceed to prove that, for any experiment \( \text{exp} \in \mathcal{E}(P) \), \( \text{exp} \subseteq_{(P,Q)} \text{exp} \) whenever there is a \((P,Q)\)-simulation relating initial states. In fact, as essentially no information is lost by \( \Rightarrow \)-transitions, we derive the more general result that any \( \Rightarrow_{P} \)-derivative of \( \text{exp} \) is simulated by any \( \Rightarrow_{Q} \)-derivative of \( \text{exp} \), where \( o \) is a \( \Rightarrow_{P} \)-derivative of \( \text{exp} \) if \( \text{exp} \Rightarrow_{P} o \). In order to accomplish that, we give a \((P,Q)\)-simulation relating \( \Rightarrow \)-derivatives of \( \text{exp} \), for any \( \text{exp} \in \mathcal{E}(P) \). But first we derive two auxiliary Lemmas which will help us to prove the first two conditions of this simulation relation (see the definition of simulation on Section 3.1).

Lemma 4.3 Let \( \text{exp} \in \mathcal{E}(P) \) and \( P \subseteq_{(P,Q)} Q \). For any \( \text{exp}pp \) and \( \text{exp}pq \) such that \( \text{exp} \Rightarrow_{P} \text{exp}pp \) and \( \text{exp} \Rightarrow_{Q} \text{exp}pq \), whenever \( (\text{exp}pq, \mathcal{Q}) \rightarrow (\text{exp}pq', \mathcal{Q}') \) then, for some \( (\text{exp}pp', \mathcal{P}') \),

\[
\langle \text{exp}pp', \mathcal{P}' \rangle \rightarrow^{*} \langle \text{exp}pp', \mathcal{P}' \rangle,
\]

\[
\langle p, \mathcal{P}' \rangle \subseteq_{(P,Q)} \langle q, \mathcal{Q}' \rangle,
\]

\[
\text{exp}pp' =_{(P,Q)} \text{exp}pq' \text{ or } \text{exp} \Rightarrow_{P} \text{exp}pp' \text{ and } \text{exp} \Rightarrow_{Q} \text{exp}pq' .
\]

By the following lemma introduces the simulation relating \( \Rightarrow \)-derivatives of an experiment \( \text{exp} \).
**Refinement Theory**

Lemma 4.5 Let $S$ be the relation consisting of $\subseteq_{(P,Q)}$ and all pairs in the form

$$((\text{exp}_{pp}, P), (\text{exp}_{pq}, Q)),$$

where $P \subseteq_{(P,Q)} Q$ and there is an $\text{exp} \in \mathcal{E}(P)$ such that $\text{exp} \models_{P} \text{exp}_{pp}$ and $\text{exp} \models_{Q} \text{exp}_{pq}$. Then $S$ is a $(P, Q)$-simulation. $\square$

Now we can prove that any $\models_{P}$-derivative of an experiment $\text{exp}$ is simulated by any $\models_{Q}$-derivative of $\text{exp}$ whenever there is a $(P, Q)$-simulation relating initial states.

**Theorem 4.6** Let $\text{exp} \in \mathcal{E}(P)$, $\text{exp} \models_{P} \text{exp}_{pp}$, and $\text{exp} \models_{Q} \text{exp}_{pq}$. Thus, if $\emptyset_{P} \subseteq_{(P,Q)} \emptyset_{Q}$ then $\text{exp}_{pp} \subseteq_{(P,Q)} \text{exp}_{pq}$. $\square$

Then we can easily derive the expected result: $\subseteq_{(P,Q)}$ includes the identity on experiments whenever there is a $(P, Q)$-simulation relating initial states.

**Corollary 4.7** Let $\text{exp} \in \mathcal{E}(P)$. Thus, if $\emptyset_{P} \subseteq_{(P,Q)} \emptyset_{Q}$ then $\text{exp} \subseteq_{(P,Q)} \text{exp}$. $\square$

### 4.2 Composition of Experiments

Following the lines of the presentation that $\subseteq_{(P,Q)}$ includes the identity on experiments whenever there is a $(P, Q)$-simulation relating initial states, now we prove the more general result that $\subseteq_{(P,Q)}$ includes the identity on composition of experiments whenever there is a $(P, Q)$-simulation relating initial states. By composition of experiments we mean a term formed by composing experiments and fully evaluated expressions with some of the constructors described in Section 2, except the atomic evaluation and (external) nondeterministic choice constructors which only preserve refinement when their arguments satisfy some specific conditions, as we will discuss later. We use $\mathcal{C}E(P)$ to denote the set of composition of experiments of a specification $P$.

As made explicit at the beginning of this section, we are interested in proving that $\text{cexp} \subseteq_{(P,Q)} \text{cexp}$, for any $\text{cexp} \in \mathcal{C}E(P)$, whenever there is a $(P, Q)$-simulation relating initial states. But, in fact, we prove the more general result that any $\models_{P}$-derivative of $\text{cexp}$ is simulated by any $\models_{Q}$-derivative of $\text{cexp}$, where the set of $\models_{P}$-derivatives of a composition of experiments $\text{cexp}$, denoted $\text{cexp} \models_{P}$, is defined by equations such as the following:

$$\text{cexp} \models_{P} = \{e | \text{cexp} \models_{P} e\}, \text{ if } \text{cexp} \in \mathcal{E}(P).$$

$$\text{cexp} \models_{P} = \{\text{cexp}\}, \text{ if } \mathcal{F}\mathcal{E}_{P}(\text{cexp}).$$

$$(\text{cexp}_{1} \parallel \text{cexp}_{2}) \models_{P} = \{e_{1} \parallel e_{2} | e_{1} \in \text{cexp}_{1} \models_{P} \text{ and } e_{2} \in \text{cexp}_{2} \models_{P}\}$$

$$(\text{cexp}_{1} ; \text{cexp}_{2}) \models_{P} = \{e_{1} ; \text{cexp}_{2} | e_{1} \in \text{cexp}_{1} \models_{P}\}$$

for any $\text{cexp}_{1}$ and $\text{cexp}_{2} \in \mathcal{C}E(P)$. Note that $\text{cexp} \in \text{cexp} \models_{P}$.

#### 4.2.1 Properties of Composition of Experiments

In order to prove the more general result, we give a $(P, Q)$-simulation relating $\models$-derivatives of $\text{cexp}$ for any $\text{cexp} \in \mathcal{C}E(P)$. The first two conditions of this simulation relation can be easily proved by using two auxiliary Lemmas similar to the ones introduced in Section 4.1.2. For space reasons, we omit the lemmas here and introduce the simulation relation directly.
Lemma 4.8 Let $S$ be the relation consisting of $\subseteq_{(P,Q)}$ and all pairs in the form
\[
((\text{cezpp}, P), (\text{cezpq}, Q)),
\]
where $P \subseteq_{(P,Q)} Q$ and there is a $\text{cezxp} \in \mathcal{CE}(P)$ such that $\text{cezpp} \in \text{cezxp} \Rightarrow_p$ and $\text{cezpq} \in \text{cezxp} \Rightarrow_q$. Then $S$ is a $(P, Q)$-simulation. $\square$

This lemma can be proved similarly to Lemma 4.5. This allows us to prove that any $\Rightarrow_p$-derivative of a composition of experiments $\text{cezxp}$ is simulated by any $\Rightarrow_q$-derivative of $\text{cezxp}$ whenever there is a $(P, Q)$-simulation relating initial states.

Theorem 4.9 Let $\text{cezxp} \in \mathcal{CE}(P)$, $\text{cezpp} \in \text{cezxp} \Rightarrow_p$, and $\text{cezpq} \in \text{cezxp} \Rightarrow_q$. Thus, if $\emptyset_P \subseteq_{(P,Q)} \emptyset_Q$ then $\text{cezpp} \subseteq_{(P,Q)} \text{cezpq}$. $\square$

This theorem can be proved similarly to Theorem 4.6. Then we can easily derive another result: $\subseteq_{(P,Q)}$ includes the identity on composition of experiments whenever there is a $(P, Q)$-simulation relating initial states.

Corollary 4.10 Let $\text{cezxp} \in \mathcal{CE}(P)$. Thus, if $\emptyset_P \subseteq_{(P,Q)} \emptyset_Q$ then $\text{cezxp} \subseteq_{(P,Q)} \text{cezxp}$. $\square$

4.3 Congruence Property of Refinement

Using the results introduced so far, it becomes easy to derive the expected congruence result. Essentially, we verify that refinement is preserved by several of the constructors introduced in Section 2. This is realized by presenting specific simulation relations.

4.3.1 Parallel Composition

First let us consider parallel composition. The following lemma is the essence of the proof that refinement is a congruence with respect to parallel composition.

Lemma 4.11 Let $S$ be the relation consisting of $\subseteq_{(P,Q)}$ and all pairs in the form
\[
((p \parallel \text{cezpp}, P), (q \parallel \text{cezpq}, Q)),
\]
where $(p, P) \subseteq_{(P,Q)} (q, Q)$ and there is a $\text{cezxp} \in \mathcal{CE}(P)$ such that $\text{cezpp} \in \text{cezxp} \Rightarrow_p$ and $\text{cezpq} \in \text{cezxp} \Rightarrow_q$. Then $S$ is a $(P, Q)$-simulation. $\square$

Using this lemma we can easily verify that refinement is preserved by the parallel composition of derivatives of the same composition of experiments. This is a general compositionality result.

Theorem 4.12 Let $\text{cezxp} \in \mathcal{CE}(P)$, $\text{cezpp} \in \text{cezxp} \Rightarrow_p$, and $\text{cezpq} \in \text{cezxp} \Rightarrow_q$.

If $p \subseteq_{(P,Q)} q$ then $p \parallel \text{cezpp} \subseteq_{(P,Q)} q \parallel \text{cezpq}$. $\square$

Finally we obtain the promised compositionality result, by specializing the result above.

Corollary 4.13 Let $\text{cezxp} \in \mathcal{CE}(P)$. If $p \subseteq_{(P,Q)} q$ then $p \parallel \text{cezxp} \subseteq_{(P,Q)} q \parallel \text{cezxp}$. $\square$
There is also a symmetric result for parallel composition:

**Theorem 4.14** Let \( cexp \in CE(P) \). If \( p \sqsubseteq_{(P,Q)} q \) then \( cexp \parallel p \sqsubseteq_{(P,Q)} cexp \parallel q \). □

It can be derived following exactly the same line sketched above. Similarly, we can prove that refinement of expressions is a congruence with respect to the constructors introduced in Section 2; we omit the details here.

### 4.3.2 Atomic Evaluation

Contrasting with the other constructors, atomic evaluation is unary. So the congruence property is expressed in the following way: \( p \sqsubseteq_{(P,Q)} q \) implies \([p] \sqsubseteq_{(P,Q)} [q]\).

Note that, by Corollary 4.10, this property immediately implies that

\[[cexp] \sqsubseteq_{(P,Q)} [cexp],\]

for any \( cexp \in CE(P) \), whenever \( \emptyset_p \sqsubseteq_{(P,Q)} \emptyset_q \).

Indeed, the congruence property stated above does not hold because the behaviour of the atomic evaluation constructor depends on whether its argument always terminates and whether it can be fully evaluated, whereas those aspects are abstracted by our definition of refinement. In fact, an expression \([q]\) only blocks (i.e., its evaluation does not lead to any state and the expression is not fully evaluated) in a state \( D \) if the evaluation of \( q \) in this state always terminates and never yields a fully evaluated expression. On the other hand, it is easy to check that a blocking state \( \langle q, D \rangle \) may be a refinement of a state \( \langle p, D \rangle \) that might either lead to \( \langle q, D \rangle \), yield a result, or diverge. In this case, \( \langle [q], D \rangle \) is not a refinement of \( \langle [p], D \rangle \), since the first configuration blocks whereas the second does not.

Naturally, a notion of refinement considering the aspects discussed above would be a congruence with respect to the atomic evaluation constructor. In fact, such a more concrete notion of refinement can be obtained by extending our definition of refinement in a very simple and natural way. Using our definition of refinement, we can only establish a weaker compositionality result. Indeed, refinement is only preserved by the atomic evaluation constructor if the arguments of this constructor satisfy some conditions, corresponding to the aspects discussed above. This is formalized by the following simulation, where we write \( NFEP(P) \) to indicate that \( P \) never fully evaluates; formally, \( NFEP(P) \) if

\[\text{whenever } P \rightarrow_p^* P' \not\rightarrow_p \text{ then } \neg NFEP(P').\]

Also, we write \( \downarrow_P P \) to indicate that \( P \) is terminating.

**Lemma 4.15** Let \( S \) be the relation consisting of \( \subseteq_{(P,Q)} \) and all pairs in the form

\[\langle [p], P \rangle, \langle [q], Q \rangle,\]

where \( \langle p, P \rangle \subseteq_{(P,Q)} \langle q, Q \rangle \) and, for any \( D \) and \( D' \) such that \( D \subseteq_{(P,Q)} D' \),

- \( \downarrow_Q \langle q, D' \rangle \) implies \( \downarrow_P \langle p, D \rangle \), and
- \( NFQQ(\langle q, D' \rangle) \) implies \( NFEP(\langle p, D \rangle) \).
Then $S$ is a $(P, Q)$-simulation. □

Now we can easily establish the weaker compositionality result for the atomic evaluation constructor.

**Theorem 4.16** For any $D$ and $D'$ such that $D \subseteq_{(P, Q)} D'$, if

$$NF\mathcal{E}_Q((q, D')) \implies NF\mathcal{E}_P((p, D)),$$

and $\downarrow Q(q, D')$ implies $\downarrow P(p, D)$ then

$$P \subseteq_{(P, Q)} q \text{ implies } [p] \subseteq_{(P, Q)} [q].$$

□

### 4.3.3 Nondeterministic Choice

The notion of refinement introduced in [3] and discussed in Section 3 abstracts from the power of expressions of making external choices; that is, an expression that cannot make an external choice (it always blocks) may be refined by an expression that can always make choices (it never blocks). Indeed, a blocked state $P$ may be refined by a state $Q$ that eventually reaches $P$, since by the definition of simulation $\rightarrow$-transitions from $Q$ may be matched by zero $\rightarrow$-transitions from $P$.

This suggests that the notion of refinement mentioned above is not preserved by external choice. In fact, it is not. For example, let $p$ and $q$ be expressions such that $p \subseteq q$ and $q$ can make choices whereas $p$ cannot. Also, assume that $cezp$ is a non fully evaluated composition of experiments. So $p \nmid cexp$ can only lead to an expression $cezp'$ derived from $cezp$, whereas $q \nmid cexp$ can either lead to $cezp'$ or to an expression $q'$ derived from $q$. Therefore, as there is a transition from $q \nmid cexp$ that cannot be matched by $p \nmid cexp$, we must conclude that the first expression is not a refinement of the second.

A notion of refinement that does not abstract from the power of expressions of making external choices can be easily derived from the notion of refinement presented in [3], by essentially requiring initial transitions from an expression to be matched by at least one transition (instead of zero or many) from a related expression. That would be preserved by the external choice method combiner.

Here we shall be content to show that the notion of refinement we are using in this article is preserved by the internal choice method combiner, which is defined in the following way:

$$P \text{ Or } Q = (\text{skip } ; P) \nmid (\text{skip } ; Q) .$$

where $P$ and $Q$ are variables and skip is any operation that does nothing and always terminate. This constructor preserves our notion of refinement because its behaviour does not depend on the behaviour of its arguments. This is a quite satisfactory result since internal choice seems to be more useful than external choice in the context of object-oriented languages [2]. The following simulation is the first step towards deriving this result.
Lemma 4.17 Let $S$ be the relation consisting of $\subseteq_{(P,Q)}$ and all pairs in the forms

- $(⟨p \text{ Or } q, P⟩, (q \text{ Or } r, Q))$,
- $(⟨\text{skip}; p \text{ Or } q, P⟩, (\text{skip}; q \text{ Or } r, Q))$,
- $(⟨q, Q⟩, (q, Q))$,
- $(⟨\text{skip}; q, Q⟩, (\text{skip}; q, Q))$,
- $(⟨q, Q⟩, (q, Q))$,
- $(⟨\text{skip}; q, Q⟩, (\text{skip}; q, Q))$,

where $(p, P) \subseteq_{(P,Q)} (q, Q)$ and there is a $\text{cezpp} \in \mathcal{CE}(P)$ such that $\text{cezpp} \in \text{cezpp} \Rightarrow^*_p$ and $\text{cezpp} \in \text{cezpp} \Rightarrow^*_q$. Then $S$ is a $(P, Q)$-simulation.

We can then easily verify that the internal choice method combiner preserves refinement, following an approach similar to the one followed for parallel composition. First we derive a general compositionality result.

Theorem 4.18 Let $\text{cezpp} \in \mathcal{CE}(P)$, $\text{cezpp} \in \text{cezpp} \Rightarrow^*_p$, and $\text{cezpp} \in \text{cezpp} \Rightarrow^*_q$. If $p \subseteq_{(P,Q)} q$ then

$$p \text{ Or } \text{cezpp} \subseteq_{(P,Q)} q \text{ Or } \text{cezpp}$$

And finally, by a trivial specialization, the desired compositionality result.

Corollary 4.19 Let $\text{cezpp} \in \mathcal{CE}(P)$. If $p \subseteq_{(P,Q)} q$ then $p \text{ Or } \text{cezpp} \subseteq_{(P,Q)} q \text{ Or } \text{cezpp}$

Symmetric results could be obtained in a similar way.

5 Other Compositionality Properties

The basic compositionality properties of standard programming language constructors were established in previous sections, by showing that refinement is preserved by them. In this section we show how other compositionality properties can be derived from the basic properties. We use the sequential composition constructor in the examples. Similar results can be derived for other constructors.

First let us assume the basic compositionality properties of sequential composition: if $p \subseteq_{(P,Q)} q$ then, for any $\text{cezpp} \in \mathcal{CE}(P)$,

$$p ; \text{cezpp} \subseteq_{(P,Q)} q ; \text{cezpp} \text{ and } \text{cezpp} ; p \subseteq_{(P,Q)} \text{cezpp} ; q.$$ 

As briefly discussed before, this result depends crucially on the condition $\text{cezpp} \in \mathcal{CE}(P)$, since our notion of refinement is based on the observational behaviour of states with respect to a restricted group of experiments.

Now consider the following compositionality property:

$$p \subseteq_{(P,Q)} q \text{ and } p' \subseteq_{(P,Q)} q'$$

implies

$$p ; p' \subseteq_{(P,Q)} q ; q'.$$

In general, this property is not valid because $p' \subseteq_{(P,Q)} q'$ essentially indicates that $p'$ is simulated by $q'$ when they are evaluated in reachable database states related by $\subseteq_{(P,Q)}$,
whereas \( p \subseteq_{(P,Q)} q \) just indicates that the evaluation of \( p \) and \( q \) in reachable states related by \( \subseteq_{(P,Q)} \) leads to states related by \( \subseteq_{(P,Q)} \); but note that those resulting states are not necessarily reachable, since \( p \) and \( q \) might not be formed exclusively by experiments. So we cannot always expect \( p ; p' \) to be simulated by \( q ; q' \). On the other hand, the congruence result is valid because \( cexp \in CE(P) \) is simulated by \( cexp \) when they are evaluated in any states related by \( \subseteq_{(P,Q)} \) (see Lemma 4.8), if reachable or not.

Although the compositionality property stated above is not valid, the following weaker version of it is indeed valid: for \( q, p' \in CE(P) \),

\[
p \subseteq_{(P,P)} q \text{ and } p' \subseteq_{(P,Q)} q'
\]

implies

\[
p ; p' \subseteq_{(P,Q)} q ; q'.
\]

It follows from the general transitivity property of \( \subseteq_{(P,Q)} \) (discussed on Sections 3.2 and 3.3) since, under the conditions stated above, by the basic compositionality properties of sequential composition, we have

\[
p ; p' \subseteq_{(P,P)} q ; p' \text{ and } q \equiv_{(P,Q)} q'.
\]

A similar property can be derived in the same way by assuming that \( q', p \in CE(P) \) instead of \( q, p' \in CE(P) \). In fact, those properties would even be valid for \( \Rightarrow \)-derivatives of the composition of experiments.

Many other compositionality properties could be easily derived as well. It is important to note that a particular group of those properties can be used to suggest a specific methodology for formal development of object-oriented software. In this article we limit ourselves to give the basis for deriving those properties.

6 Conclusions

We established several properties of the notion of refinement introduced in [3]. In particular, we proved that the relation of refinement of expressions is a congruence with respect to several standard programming language constructors. We also explained how to derive novel compositionality results from the basic congruence result. The congruence property justifies the compositional verification and derivation of implementations; this is essential for formal development of complex systems in practice. However, we only considered compositionality in the small; properties of compositionality in the large are related to the semantics of module systems, which was not discussed in this article.

The proof of the congruence result justified and provided a deep insight into some of the technical decisions adopted in [3]. For instance, by analysing the proof we could conclude that the congruence result can only be obtained if experiments have an atomic and terminating nature. Moreover, we indicated that atomicity of experiments does not necessarily mean that experiments have to be evaluated in one state transition. Instead, the fully evaluation of an experiment may take many transitions, as long as the only (if any) transition that depends on the state or corresponds to a nondeterministic choice is the last one. That is the essence of atomicity.
We could also conclude that the congruence property is only valid for contexts formed by visible operations (experiments). In fact, this should be expected for any notion of refinement based on the observational behaviour of states with respect to a restricted group of visible operations. In particular, refinement is not a congruence with respect to contexts formed by user defined method combiners, since they might just be abbreviations for a combination of hidden operations.

We explained why refinement is not a congruence with respect to the atomic evaluation and nondeterministic external choice constructors. Basically, the behaviour of those constructors depends on some aspects which are abstracted by the notion of refinement explored in this article. However, we verified that nondeterministic internal choice preserves refinement, and a weaker compositionality result is valid for the atomic evaluation constructor. Indeed, this weaker result indicates how the atomic evaluation constructor should be used in practice. Lastly, we concluded that refinement is not in general a congruence with respect to visible operations (methods and attributes), since does not necessarily imply that and have the same or related types; in fact, this depends on the type system of a particular language. So, for a visible operation , might be a well formed term whereas is not.

In [1], the general results presented in this article have been specialized to prove that FOOPS' notion of refinement is a congruence with respect to most constructors of that language. Those results are not proposed as the only tools that should be available for formal software development; instead, it is indeed a basis for the definition of refinement calculi [11] and methodologies for formal development of concurrent object-oriented software.

In fact, just a few notions of refinement of concurrent object-oriented programs have been proposed so far. We will comment on two of those notions, concluding that none of them provide a general definition of refinement with compositionality results such as the ones presented here. One of them [7], actually considers only refinement of object based concurrent programs, presenting many examples of formal development of programs. Most examples are simple and elegant, and use a few refinement preserving transformation rules. However, no general definition of refinement is proposed; although the semantics of the language presented in [7] is given in terms of a process algebra, the notions of equivalence and refinement of the algebra cannot be directly used to define the notion of refinement of the language [8].

Another approach for refinement of object oriented concurrent programs is described in [9], which gives an overview of a general notion of refinement for a concurrent object oriented specification language. This notion of refinement is compositional in the large. However, compositionality in the small, as considered here, and proof techniques are not discussed.
